Tanzania Tourism Expenditure Prediction

Executive Report

Machine Learning Project · Internal · Confidential

4,809	−40%	0.395	80%
tourist records analysed	prediction error vs baseline	R^2 — variance explained	tourists within ±100%

All values in Tanzanian Shillings (TZS). 1,000,000 TZS ≈ 345 EUR.

1. Executive Summary

This report presents the findings of a machine learning project undertaken to predict tourist expenditure in Tanzania. Using historical records of 4,809 tourists, we built and evaluated a series of AI models that can estimate how much a tourist will spend based on their booking profile — before they arrive.

The best-performing model (XGBoost, tuned) reduces prediction error by 40% compared to the naive approach of always guessing the average spend. On unseen data it achieves a Mean Absolute Error of 4.55 million TZS and explains 39.5% of the variation in tourist spending.

Critically, the analysis reveals that the most important driver of tourist spending is not country of origin — the traditional focus of marketing decisions — but tour arrangement type and duration of stay. This finding has direct implications for how the Tanzania Tourism Board allocates marketing budget and designs tour packages.

Three strategic recommendations:

- Redesign marketing segments around trip type (Independent vs Package), not just country of origin.
- Invest in campaigns that extend average stay duration — stronger revenue impact than attracting more short-stay tourists.
- Deploy the model in tour operator booking systems for real-time spend forecasting and revenue planning.

2. The Business Problem

Tanzania's tourism sector contributes approximately 17% of GDP and 25% of foreign exchange revenues, employing over 600,000 people directly. Accurate forecasting of tourist spending is critical for marketing investment decisions, package design, infrastructure planning, and revenue projection.

The central question this project addresses: given a tourist's booking profile — country of origin, type of tour arrangement, intended stay duration, group size, and package inclusions — can we reliably estimate how much they will spend?

2.1 Why this is a hard problem

Tourist spending does not follow a simple pattern. Most visitors spend between 500,000 and 10 million TZS. But a small group of "whale" tourists spend 50 to 99 million TZS — more than 100 times what a budget visitor spends. This extreme variation makes prediction genuinely difficult, and means standard statistical approaches perform poorly.

3. Our Approach

We followed a rigorous six-step pipeline designed to produce an honest, unbiased model whose performance metrics reflect real-world prediction accuracy.

Step 1: Data cleaning

The raw dataset contained typos, an Excel date-formatting error, missing values in 23% of the "travel companion" column, and records with zero people listed. All corrected using transparent rule-based fixes before any modelling began.

Step 2: Train / validation / test split

The 4,809 tourists were divided: 70% training (3,366), 15% validation (721), 15% sealed test set (722). The test set was opened only once — at the very end — to produce the final performance scores. This prevents inflated accuracy from inadvertently optimising on test data.

Step 3: Feature engineering and preprocessing

All statistics used to transform the data were calculated from the training set only, then applied to all three sets. Text features were one-hot encoded, numerical features scaled, and the target (spend) log-transformed to handle extreme skew.

Step 4 & 5: Train and tune three model families

Ridge Regression (linear formula), Random Forest (hundreds of independent decision trees), and XGBoost (sequential trees each correcting the previous) were trained then tuned by systematically testing dozens of parameter combinations.

Step 6: Explainability (SHAP)

For the winning model we applied SHAP analysis: for every prediction it calculates exactly how much each feature pushed the result up or down. This makes every forecast fully auditable and explainable to non-technical stakeholders.

4. Results

4.1 Model comparison

All seven model configurations were evaluated on the sealed test set. MAE = average absolute error in TZS. R^2 = proportion of spending variation explained.

Model	Test MAE	vs Baseline	Test R^2	Rank
Baseline (always guess mean)	7,642,071 TZS	—	0.000	#7
Ridge — pre-tuning (α=1)	4,759,126 TZS	+37.7%	0.365	#5
Ridge — tuned (α=5)	4,758,358 TZS	+37.7%	0.364	#4
Random Forest — pre-tuning	4,700,036 TZS	+38.5%	0.355	#6
Random Forest — tuned	4,608,597 TZS	+39.7%	0.358	#2
XGBoost — pre-tuning	4,585,876 TZS	+40.0%	0.415	#3
XGBoost — tuned ★ (winner)	**4,550,721 TZS**	**+40.4%**	**0.395**	**#1**

The tuned XGBoost model is the clear winner: lowest MAE, smallest overfitting gap (0.47M TZS), and strong R^2.

Note on R^2: XGBoost pre-tuning achieves R^2=0.415 vs tuned 0.395. The metrics can disagree slightly due to how they handle extreme outliers. MAE is the primary metric as it speaks directly in TZS.

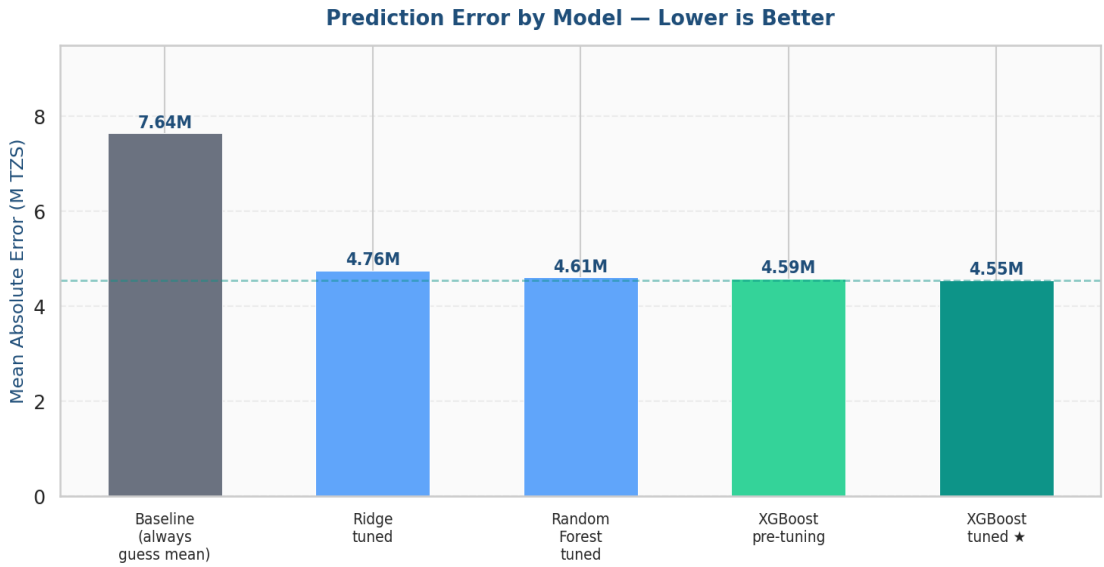

Figure 1: Test set MAE across all 7 model configurations. Lower is better.

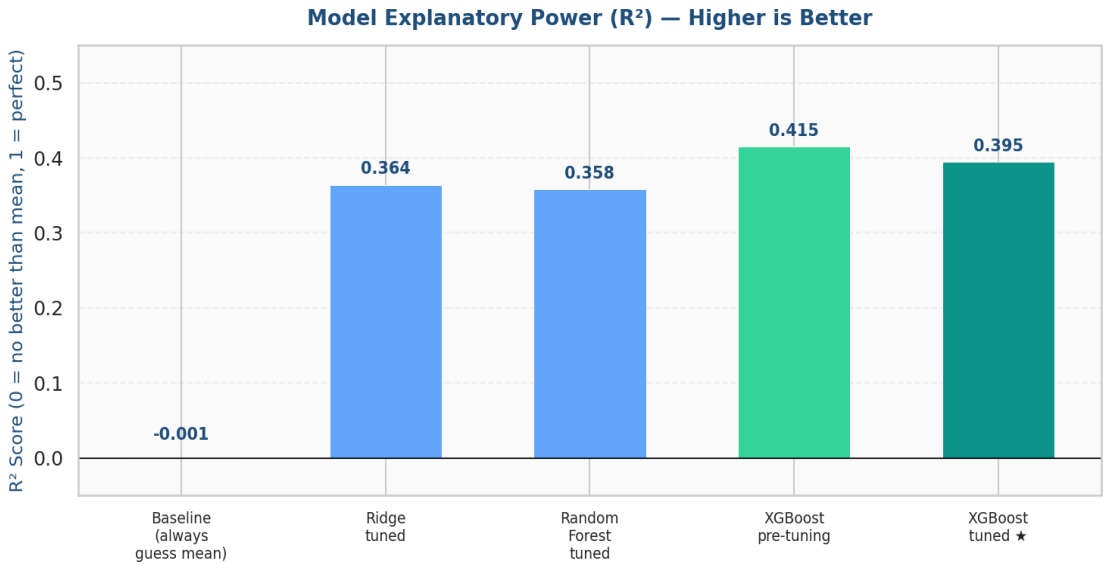

Figure 2: R^2 score across all configurations. Higher is better.

4.2 Prediction accuracy in plain terms

- 47% of tourists predicted within 50% of their actual spend
- 80% of tourists predicted within 100% of their actual spend
- The model is unbiased on average — no systematic over or under-prediction
- Largest errors concentrated in luxury Leisure trips (50M–90M TZS) where training data is sparse

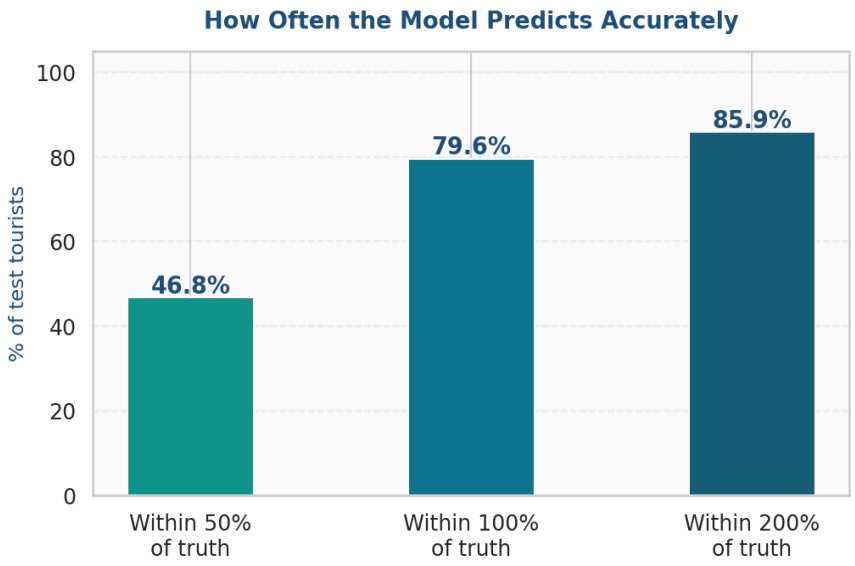

Figure 3: Proportion of test tourists predicted within different accuracy bands.

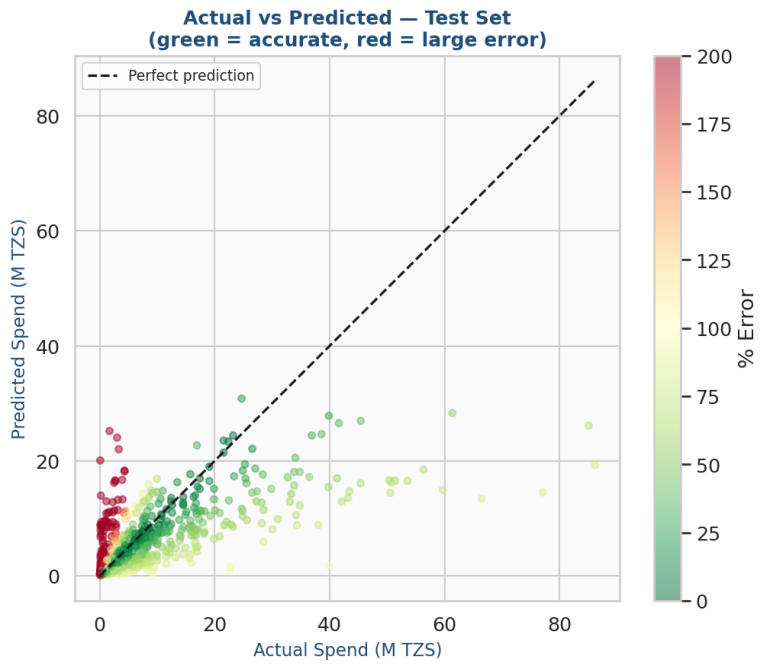

Figure 4: Actual vs predicted spend. Dots on the diagonal = perfect. Red cluster (top right) = luxury trips the model underestimates.

5. What Drives Tourist Spending?

The SHAP analysis reveals a clear hierarchy. Country of origin — which typically dominates marketing thinking — is not in the top 5 drivers.

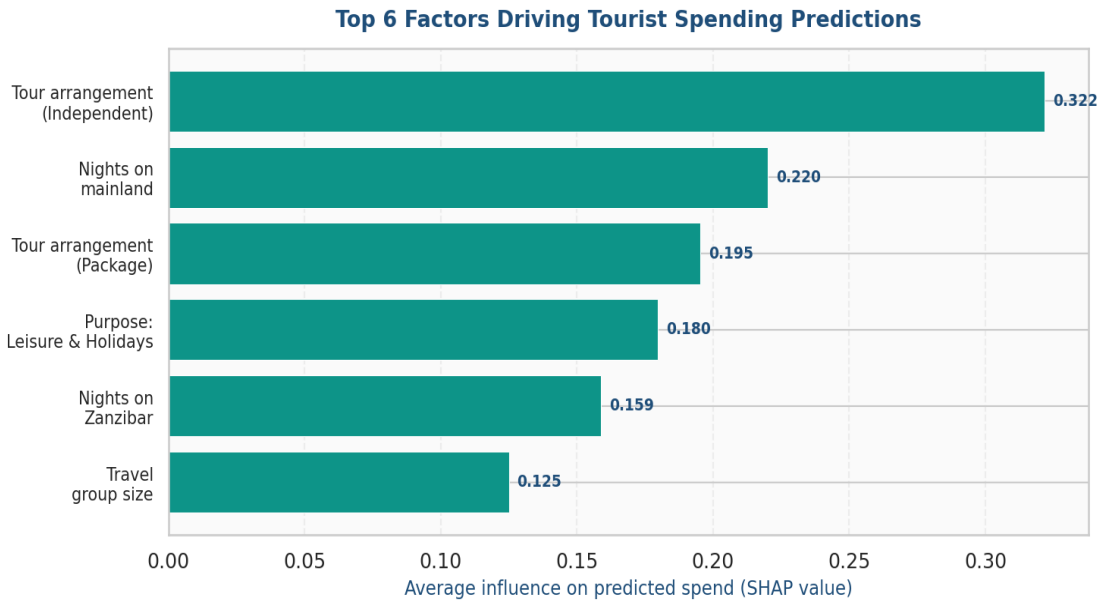

Figure 5: Top 6 features by average SHAP influence. Bar length = average impact on predicted spend.

5.1 Top 5 factors explained

1. **Tour arrangement (Independent vs Package) — SHAP: 0.32**

The strongest signal. Whether a tourist books independently or on a package shifts predicted spend by roughly ±35%. These two tourist types have fundamentally different spending profiles.

2. **Nights on mainland — SHAP: 0.22**

Every additional night on mainland Tanzania consistently raises predicted spend. The relationship is nearly linear with no diminishing returns within the typical stay range.

3. **Tour arrangement (Package Tour) — SHAP: 0.20**

Tourists on full package deals — accommodation, transport, meals bundled — are predicted to spend substantially more in total.

4. **Purpose: Leisure and Holidays — SHAP: 0.18**

Leisure tourists are predicted to spend more than business visitors, family visitors, or volunteers. Purpose adds meaningful signal beyond tour arrangement alone.

5. **Nights on Zanzibar — SHAP: 0.16**

Identical logic to mainland nights. Tourists visiting both mainland Tanzania and Zanzibar have higher predicted spend than those visiting only one destination.

6. Strategic Recommendations

Recommendation 1: Shift the marketing lens from country to trip type

Tour arrangement is a stronger predictor of spend than country of origin. A Danish tourist on a two-night independent trip may spend less than a Ugandan tourist on a 14-night all-inclusive package.

Proposed action: *Develop separate marketing tracks, pricing tiers, and conversion funnels for Independent vs Package tourist segments. Measure campaign ROI in terms of predicted spend, not just arrivals.*

Recommendation 2: Prioritise stay extension over headcount growth

Nights on mainland and Zanzibar are the 2nd and 3rd most important predictors. A tourist extending from 7 to 14 nights is predicted to spend substantially more — with no additional acquisition cost.

Proposed action: *Design and promote multi-destination itineraries combining mainland safari with Zanzibar beach stays. Partner with airlines on stopover packages that extend effective stay at minimal tourist cost.*

Recommendation 3: Deploy the model for live revenue forecasting

The model is production-ready. Any tour operator or booking system can input a booking profile and receive a predicted spend estimate — enabling proactive revenue planning, personalised upsell offers, and better infrastructure allocation.

Proposed action: *Integrate the model as an API endpoint into tour operator booking systems. Use predictions to identify high-value tourists for premium concierge outreach before arrival.*

7. Known Limitations

- Model explains ~40% of spending variation. The remaining 60% is driven by factors not in the available data — accommodation tier, exchange rates, individual discretionary choices, undisclosed cash spending.
- Luxury trips (50M–90M TZS) are consistently under-predicted — too few training examples at this extreme.
- The model reflects patterns in the training data and should be retrained periodically — ideally annually — as travel patterns evolve.
- All figures are in Tanzanian Shillings. Exchange rate fluctuations affect EUR/USD equivalents but not TZS predictions.

8. Technical Appendix

Data

- Source: Train.csv (Tanzania Tourism Board)
- 4,809 rows × 23 columns. Target: total_cost (TZS)
- Split: 70/15/15 (train/val/test), random_state=42

Winning model

- Algorithm: XGBoost Regressor
- Key parameters: n_estimators=300, learning_rate=0.02, max_depth=6, subsample=0.75
- Target transformation: log1p(total_cost), back-transformed for reporting
- Features after encoding: 88 (21 original columns → one-hot expanded)

Metrics (test set)

- MAE: 4,550,721 TZS (~1,570 EUR)
- R^2: 0.395 (39.5% of variation explained)
- MdAPE: 52.7% (median absolute percentage error)
- 80% of tourists predicted within 100% of actual spend

Software

- Python 3.10+, scikit-learn 1.8.0, xgboost 3.2.0, shap 0.51.0
- Full reproducible notebook: Tanzania_Tourism_v3.ipynb
